Abstract—We study Markov decision processes (MDPs) with multiple limit-average (or mean-payoff) functions. We consider two different objectives, namely, expectation and satisfaction objectives. Given an MDP with k reward functions, in the expectation objective the goal is to maximize the expected limit-average value, and in the satisfaction objective the goal is to maximize the probability of runs such that the limit-average value stays above a given vector. We show that under the expectation objective, in contrast to the single-objective case, both randomization and memory are necessary for strategies, and that finite-memory randomized strategies are sufficient. Under the satisfaction objective, in contrast to the single-objective case, infinite memory is necessary for strategies, and that randomized memoryless strategies are sufficient for ε -approximation, for all $\varepsilon > 0$. We further prove that the decision problems for both expectation and satisfaction objectives can be solved in polynomial time and the trade-off curve (Pareto curve) can be ε -approximated in time polynomial in the size of the MDP and $\frac{1}{\varepsilon}$, and exponential in the number of reward functions, for all $\varepsilon > 0$. Our results also reveal flaws in previous work for MDPs with multiple mean-payoff functions under the expectation objective, correct the flaws and obtain improved results.

I. INTRODUCTION

Markov decision processes (MDPs) are the standard models for probabilistic dynamic systems that exhibit both probabilistic and nondeterministic behaviors [14], [7]. In each state of an MDP, a controller chooses one of several actions (the nondeterministic choices), and the system stochastically evolves to a new state based on the current state and the chosen action. A reward (or cost) is associated with each transition and the central question is to find a strategy of choosing the actions that optimizes the rewards obtained over the run of the system. One classical way to combine the rewards over the run of the system is the *limit-average (or mean-payoff)* function that assigns to every run the long-run average of the rewards over the run. MDPs with single mean-payoff functions have been widely studied in literature (see, e.g., [14], [7]). In many modeling domains, however, there is not a single goal to be optimized, but multiple, potentially dependent and conflicting goals. For example, in designing a computer system, the goal is to maximize average performance while minimizing average power consumption. Similarly, in an inventory management system, the goal is to optimize several potentially dependent costs for maintaining each kind of product. These motivate the study of MDPs with multiple mean-payoff functions.

Traditionally, MDPs with mean-payoff functions have been studied with only the *expectation* objective, where the goal is to maximize (or minimize) the expectation of the mean-payoff function. There are numerous applications of MDPs with expectation objectives in inventory control, planning, and performance evaluation [14], [7]. In this work we consider both the expectation objective and also the *satisfaction* objective for a given MDP. In both cases we are given an MDP with k reward functions, and the goal is to maximize (or minimize) either the k -tuple of expectations, or the probability of runs such that the mean-payoff value stays above a given vector.

To get some intuition about the difference between the expectation/satisfaction objectives and to show that in some scenarios the satisfaction objective is preferable, consider a filehosting system where the users can download files at various speed, depending on the current setup and the number of connected customers. For simplicity, let us assume that a user has 20% chance to get a 2000kB/sec connection, and 80% chance to get a slow 20kB/sec connection. Then, the overall performance of the server can be reasonably measured by the expected amount of transferred data per user and second (i.e., the expected mean payoff) which is 416kB/sec. However, a single user is more interested in her chance of downloading the files quickly, which can be measured by the probability of establishing and maintaining a reasonably fast connection (say, ≥ 1500 kB/sec). Hence, the system administrator may want to maximize the expected mean payoff (by changing the internal setup of the system), while a single user aims at maximizing the probability of satisfying her preferences (she can achieve that, e.g., by buying a priority access, waiting till 3 a.m., or simply connecting to a different server; obviously, she might also wish to minimize other mean payoffs such as the price per transferred bit). In other words, the expectation objective is relevant in situations when we are interested in the “average” behaviour of many instances of a given system, while the satisfaction objective is useful for analyzing and optimizing particular executions.

In MDPs with multiple mean-payoff functions, various strategies may produce incomparable solutions, and consequently there is no “best” solution in general. Informally, the set of *achievable solutions*

- (i) under the expectation objective is the set of all vectors \vec{v}

- such that there is a strategy to ensure that the expected mean-payoff value vector under the strategy is at least \vec{v} ;
- (ii) under the satisfaction objective is the set of tuples (ν, \vec{v}) where $\nu \in [0, 1]$ and \vec{v} is a vector such that there is a strategy under which with probability at least ν the mean-payoff value vector of a run is at least \vec{v} .

The “trade-offs” among the goals represented by the individual mean-payoff functions are formally captured by the *Pareto curve*, which consists of all minimal tuples (wrt. componentwise ordering) that are not strictly dominated by any achievable solution. Intuitively, the Pareto curve consists of “limits” of achievable solutions, and in principle it may contain tuples that are not achievable solutions (see Section III). Pareto optimality has been studied in cooperative game theory [12] and in multi-criterion optimization and decision making in both economics and engineering [10], [17], [16].

Our study of MDPs with multiple mean-payoff functions is motivated by the following fundamental questions, which concern both basic properties and algorithmic aspects of the expectation/satisfaction objectives:

- Q.1 What type of strategies is sufficient (and necessary) for achievable solutions?
- Q.2 Are the elements of the Pareto curve achievable solutions?
- Q.3 Is it decidable whether a given vector represents an achievable solution?
- Q.4 Given an achievable solution, is it possible to compute a strategy which achieves this solution?
- Q.5 Is it decidable whether a given vector belongs to the Pareto curve?
- Q.6 Is it possible to compute a finite representation/approximation of the Pareto curve?

We provide comprehensive answers to the above questions, both for the expectation and the satisfaction objective. We also analyze the complexity of the problems given in Q.3–Q.6. From a practical point of view, it is particularly encouraging that most of the considered problems turn out to be solvable *efficiently*, i.e., in polynomial time. More concretely, our answers to Q.1–Q.6 are the following:

- 1a. For the expectation objectives, finite-memory strategies are sufficient and necessary for all achievable solutions.
- 1b. For the satisfaction objectives, achievable solutions require infinite memory in general, but memoryless randomized strategies are sufficient to approximate any achievable solution up to an arbitrarily small $\varepsilon > 0$.
2. All elements of the Pareto curve are achievable solutions.
3. The problem whether a given vector represents an achievable solution is solvable in polynomial time.
- 4.a For the expectation objectives, a strategy which achieves a given solution is computable in polynomial time.
- 4.b For the satisfaction objectives, a strategy which ε -approximates a given solution is computable in polynomial time.
5. The problem whether a given vector belongs to the Pareto curve is solvable in polynomial time.
6. A finite description of the Pareto curve is computable in

exponential time. Further, an ε -approximate Pareto curve is computable in time which is polynomial in $1/\varepsilon$ and the size of a given MDP, and exponential in the number of mean-payoff functions.

A more detailed and precise explanation of our results is postponed to Section III.

Let us note that MDPs with multiple mean-payoff functions under the expectation objective were also studied in [3], and it was claimed that randomized memoryless strategies are sufficient for ε -approximation of the Pareto curve, for all $\varepsilon > 0$, and an NP algorithm was presented to find a randomized memoryless strategy achieving a given vector. We show with an example that under the expectation objective there exists $\varepsilon > 0$ such that randomized strategies *do require* memory for ε -approximation, and thus reveal a flaw in the earlier paper (our results not only correct the flaws of [3], but also significantly improve the complexity of the algorithm for finding a strategy achieving a given vector).

Similarly to the related papers [4], [6], [8] (see Related Work), we obtain our results by a characterization of the set of achievable solutions by a set of linear constraints, and from the linear constraints we construct witness strategies for any achievable solution. However, our approach differs significantly from the previous works. In all the previous works, the linear constraints are used to encode a *memoryless* strategy either directly for the MDP [4], or (if memoryless strategies do not suffice in general) for a finite “product” of the MDP and the specification function expressed as automata, from which the memoryless strategy is then transferred to a finite-memory strategy for the original MDP [6], [8], [5]. In our setting new problems arise. Under the expectation objective with mean-payoff function, neither is there any immediate notion of “product” of MDP and mean-payoff function and nor do memoryless strategies suffice. Moreover, even for memoryless strategies the linear constraint characterization is not straightforward for mean-payoff functions, as in the case of discounted [4], reachability [6] and total reward functions [8]: for example, in [3] even for memoryless strategies there was no linear constraint characterization for mean-payoff function and only an NP algorithm was given. Our result, obtained by a characterization of linear constraints directly on the original MDP, requires involved and intricate construction of witness strategies. Moreover, our results are significant and non-trivial generalizations of the classical results for MDPs with a single mean-payoff function, where memoryless pure optimal strategies exist, while for multiple functions both randomization and memory is necessary. Under the satisfaction objective, any finite product on which a memoryless strategy would exist is not feasible as in general witness strategies for achievable solutions may need an infinite amount of memory. We establish a correspondence between the set of achievable solutions under both types of objectives for strongly connected MDPs. Finally, we use this correspondence to obtain our result for satisfaction objectives.

Related Work. In [4] MDPs with multiple discounted reward functions were studied. It was shown that memoryless strate-

gies suffice for Pareto optimization, and a polynomial time algorithm was given to approximate (up to a given relative error) the Pareto curve by reduction to multi-objective linear-programming and using the results of [13]. MDPs with multiple qualitative ω -regular specifications were studied in [6]. It was shown that the Pareto curve can be approximated in polynomial time; the algorithm reduces the problem to MDPs with multiple reachability specifications, which can be solved by multi-objective linear-programming. In [8], the results of [6] were extended to combine ω -regular and expected total reward objectives. MDPs with multiple mean-payoff functions under expectation objectives were considered in [3], and our results reveal flaws in the earlier paper, correct the flaws, and present significantly improved results (a polynomial time algorithm for finding a strategy achieving a given vector as compared to the previously known NP algorithm). Moreover, the satisfaction objective has not been considered in multi-objective setting before, and even in single objective case it has been considered only in a very specific setting [1].

II. PRELIMINARIES

We use \mathbb{N} , \mathbb{Z} , \mathbb{Q} , and \mathbb{R} to denote the sets of positive integers, integers, rational numbers, and real numbers, respectively. Given two vectors $\vec{v}, \vec{u} \in \mathbb{R}^k$, where $k \in \mathbb{N}$, we write $\vec{v} \leq \vec{u}$ iff $\vec{v}_i \leq \vec{u}_i$ for all $1 \leq i \leq k$, and $\vec{v} < \vec{u}$ iff $\vec{v} \leq \vec{u}$ and $\vec{v}_i < \vec{u}_i$ for some $1 \leq i \leq k$.

We assume familiarity with basic notions of probability theory, e.g., *probability space*, *random variable*, or *expected value*. As usual, a *probability distribution* over a finite or countably infinite set X is a function $f : X \rightarrow [0, 1]$ such that $\sum_{x \in X} f(x) = 1$. We call f *positive* if $f(x) > 0$ for every $x \in X$, *rational* if $f(x) \in \mathbb{Q}$ for every $x \in X$, and *Dirac* if $f(x) = 1$ for some $x \in X$. The set of all distributions over X is denoted by $\text{dist}(X)$.

Markov chains. A *Markov chain* is a tuple $M = (L, \rightarrow, \mu)$ where L is a finite or countably infinite set of locations, $\rightarrow \subseteq L \times (0, 1] \times L$ is a transition relation such that for each fixed $\ell \in L$, $\sum_{\ell \xrightarrow{x} \ell'} x = 1$, and μ is the initial probability distribution on L .

A *run* in M is an infinite sequence $\omega = \ell_1 \ell_2 \dots$ of locations such that $\ell_i \xrightarrow{x_i} \ell_{i+1}$ for every $i \in \mathbb{N}$. A *finite path* in M is a finite prefix of a run. Each finite path w in M determines the set $\text{Cone}(w)$ consisting of all runs that start with w . To M we associate the probability space $(\text{Runs}_M, \mathcal{F}, \mathbb{P})$, where Runs_M is the set of all runs in M , \mathcal{F} is the σ -field generated by all $\text{Cone}(w)$, and \mathbb{P} is the unique probability measure such that $\mathbb{P}(\text{Cone}(\ell_1, \dots, \ell_k)) = \mu(\ell_1) \cdot \prod_{i=1}^{k-1} x_i$, where $\ell_i \xrightarrow{x_i} \ell_{i+1}$ for all $1 \leq i < k$ (the empty product is equal to 1).

Markov decision processes. A *Markov decision process* (MDP) is a tuple $G = (S, A, \text{Act}, \delta)$ where S is a *finite* set of states, A is a *finite* set of actions, $\text{Act} : S \rightarrow 2^A \setminus \emptyset$ is an action enabledness function that assigns to each state s the set $\text{Act}(s)$ of actions enabled at s , and $\delta : S \times A \rightarrow \text{dist}(S)$ is a probabilistic transition function that given a state s and an action $a \in \text{Act}(s)$ enabled at s gives a probability distribution over the successor states. For simplicity, we assume

that every action is enabled in exactly one state, and we denote this state $\text{Src}(a)$. Thus, henceforth we will assume that $\delta : A \rightarrow \text{dist}(S)$.

A *run* in G is an infinite alternating sequence of states and actions $\omega = s_1 a_1 s_2 a_2 \dots$ such that for all $i \geq 1$, $\text{Src}(a_i) = s_i$ and $\delta(a_i)(s_{i+1}) > 0$. We denote by Runs_G the set of all runs in G . A *finite path* of length k in G is a finite prefix $w = s_1 a_1 \dots a_{k-1} s_k$ of a run in G . For a finite path w we denote by $\text{last}(w)$ the last state of w .

A pair (T, B) with $\emptyset \neq T \subseteq S$ and $B \subseteq \bigcup_{t \in T} \text{Act}(t)$ is an *end component* of G if (1) for all $a \in B$, whenever $\delta(a)(s') > 0$ then $s' \in T$; and (2) for all $s, t \in T$ there is a finite path $\omega = s_1 a_1 \dots a_{k-1} s_k$ such that $s_1 = s$, $s_k = t$, and all states and actions that appear in w belong to T and B , respectively. (T, B) is a *maximal end component (MEC)* if it is maximal wrt. pointwise subset ordering. Given an end component $C = (T, B)$, we sometimes abuse notation by using C instead of T or B , e.g., by writing $a \in C$ instead of $a \in B$ for $a \in A$.

Strategies and plays. Intuitively, a strategy in an MDP G is a “recipe” to choose actions. Usually, a strategy is formally defined as a function $\sigma : (SA)^* S \rightarrow \text{dist}(A)$ that given a finite path w , representing the history of a play, gives a probability distribution over the actions enabled in $\text{last}(w)$. In this paper, we adopt a somewhat different (though equivalent – see Appendix E) definition, which allows a more natural classification of various strategy types. Let M be a finite or countably infinite set of *memory elements*. A *strategy* is a triple $\sigma = (\sigma_u, \sigma_n, \alpha)$, where $\sigma_u : A \times S \times M \rightarrow \text{dist}(M)$ and $\sigma_n : S \times M \rightarrow \text{dist}(A)$ are *memory update* and *next move* functions, respectively, and α is an initial distribution on memory elements. We require that for all $(s, m) \in S \times M$, the distribution $\sigma_n(s, m)$ assigns a positive value only to actions enabled at s . The set of all strategies is denoted by Σ (the underlying MDP G will be always clear from the context).

Let $s \in S$ be an initial state. A *play* of G determined by s and a strategy σ is a Markov chain G_s^σ (or just G^σ if s is clear from the context) where the set of locations is $S \times M \times A$, the initial distribution μ is positive only on (some) elements of $\{s\} \times M \times A$ where $\mu(s, m, a) = \alpha(m) \cdot \sigma_n(s, m)(a)$, and $(t, m, a) \xrightarrow{x} (t', m', a')$ iff

$$x = \delta(a)(t') \cdot \sigma_u(a, t', m)(m') \cdot \sigma_n(t', m')(a') > 0.$$

Hence, G_s^σ starts in a location chosen randomly according to α and σ_n . In a current location (t, m, a) , the next action to be performed is a , hence the probability of entering t' is $\delta(a)(t')$. The probability of updating the memory to m' is $\sigma_u(a, t', m)(m')$, and the probability of selecting a' as the next action is $\sigma_n(t', m')(a')$. We assume that these choices are independent, and thus obtain the product above.

In this paper, we consider various functions over Runs_G that become random variables over $\text{Runs}_{G_s^\sigma}$ after fixing some σ and s . For example, for $F \subseteq S$ we denote by $\text{Reach}(F) \subseteq \text{Runs}_G$ the set of all runs reaching F . Then $\text{Reach}(F)$ naturally determines $\text{Reach}_s^\sigma(F) \subseteq \text{Runs}_{G_s^\sigma}$ by simply “ignoring” the visited memory elements. To simplify and unify our notation, we write, e.g., $\mathbb{P}_s^\sigma[\text{Reach}(F)]$ instead

of $\mathbb{P}_s^\sigma[\text{Reach}_s^\sigma(F)]$, where \mathbb{P}_s^σ is the probability measure of the probability space associated to G_s^σ . We also adopt this notation for other events and functions, such as $\text{lr}_{\text{inf}}(\vec{r})$ or $\text{lr}_{\text{sup}}(\vec{r})$ defined in the next section, and write, e.g., $\mathbb{E}_s^\sigma[\text{lr}_{\text{inf}}(\vec{r})]$ instead of $\mathbb{E}[\text{lr}_{\text{inf}}(\vec{r})_s^\sigma]$.

Strategy types. In general, a strategy may use infinite memory, and both σ_u and σ_n may randomize. According to the use of randomization, a strategy, σ , can be classified as

- *pure* (or *deterministic*), if α is Dirac and both the memory update and the next move function give a Dirac distribution for every argument;
- *deterministic-update*, if α is Dirac and the memory update function gives a Dirac distribution for every argument;
- *stochastic-update*, if α , σ_u , and σ_n are unrestricted.

Note that every pure strategy is deterministic-update, and every deterministic-update strategy is stochastic-update. A *randomized* strategy is a strategy which is not necessarily pure. We also classify the strategies according to the size of memory they use. Important subclasses are *memoryless* strategies, in which M is a singleton, *n -memory* strategies, in which M has exactly n elements, and *finite-memory* strategies, in which M is finite. By Σ^M we denote the set of all memoryless strategies. Memoryless strategies can be specified as $\sigma : S \rightarrow \text{dist}(A)$. *Memoryless pure* strategies, i.e., those which are both pure and memoryless, can be specified as $\sigma : S \rightarrow A$.

For a finite-memory strategy σ , a *bottom strongly connected component* (BSCC) of G_s^σ is a subset of locations $W \subseteq S \times M \times A$ such that for all $\ell_1 \in W$ and $\ell_2 \in S \times M \times A$ we have that (i) if ℓ_2 is reachable from ℓ_1 , then $\ell_2 \in W$, and (ii) for all $\ell_1, \ell_2 \in W$ we have that ℓ_2 is reachable from ℓ_1 . Every BSCC W determines a unique end component $(\{s \mid (s, m, a) \in W\}, \{a \mid (s, m, a) \in W\})$ of G , and we sometimes do not strictly distinguish between W and its associated end component.

As we already noted, stochastic-update strategies can be easily translated into “ordinary” strategies of the form $\sigma : (SA)^*S \rightarrow \text{dist}(A)$, and vice versa (see Appendix E). Note that a finite-memory stochastic-update strategy σ can be easily implemented by a *stochastic finite-state automaton* that scans the history of a play “on the fly” (in fact, G_s^σ simulates this automaton). Hence, finite-memory stochastic-update strategies can be seen as natural extensions of ordinary (i.e., deterministic-update) finite-memory strategies that are implemented by deterministic finite-state automata.

A running example (I). As an example, consider the MDP $G = (S, A, \text{Act}, \delta)$ of Fig. 1a. Here, $S = \{s_1, \dots, s_4\}$, $A = \{a_1, \dots, a_6\}$, Act is denoted using the labels on lines going from actions, e.g., $\text{Act}(s_1) = \{a_1, a_2\}$, and δ is given by the arrows, e.g., $\delta(a_4)(s_4) = 0.3$. Note that G has four end components (two different on $\{s_3, s_4\}$) and two MECs.

Let s_1 be the initial state and $M = \{m_1, m_2\}$. Consider a stochastic-update finite-memory strategy $\sigma = (\sigma_u, \sigma_n, \alpha)$ where α chooses m_1 deterministically, and $\sigma_n(m_1, s_1) = [a_1 \mapsto 0.5, a_2 \mapsto 0.5]$, $\sigma_n(m_2, s_3) = [a_4 \mapsto 1]$ and otherwise σ_n chooses self-loops. The memory update function σ_u leaves the memory intact except for the case $\sigma_u(m_1, s_3)$ where both

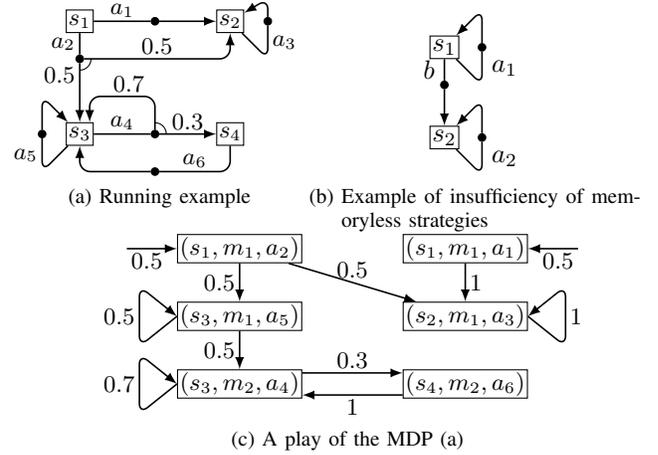

Fig. 1: Example MDPs

m_1 and m_2 are chosen with probability 0.5. The play $G_{s_1}^\sigma$ is depicted in Fig. 1c.

III. MAIN RESULTS

In this paper we establish basic results about Markov decision processes with *expectation* and *satisfaction* objectives specified by multiple *limit average* (or *mean payoff*) functions. We adopt the variant where rewards are assigned to edges (i.e., actions) rather than states of a given MDP.

Let $G = (S, A, \text{Act}, \delta)$ be a MDP, and $r : A \rightarrow \mathbb{Q}$ a *reward function*. Note that r may also take negative values. For every $j \in \mathbb{N}$, let $A_j : \text{Runs}_G \rightarrow A$ be a function which to every run $\omega \in \text{Runs}_G$ assigns the j -th action of ω . Since the limit average function $\text{lr}(r) : \text{Runs}_G \rightarrow \mathbb{R}$ given by

$$\text{lr}(r)(\omega) = \lim_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T r(A_t(\omega))$$

may be undefined for some runs, we consider its lower and upper approximation $\text{lr}_{\text{inf}}(r)$ and $\text{lr}_{\text{sup}}(r)$ that are defined for *all* $\omega \in \text{Runs}$ as follows:

$$\begin{aligned} \text{lr}_{\text{inf}}(r)(\omega) &= \liminf_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T r(A_t(\omega)), \\ \text{lr}_{\text{sup}}(r)(\omega) &= \limsup_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T r(A_t(\omega)). \end{aligned}$$

For a vector $\vec{r} = (r_1, \dots, r_k)$ of reward functions, we similarly define the \mathbb{R}^k -valued functions

$$\begin{aligned} \text{lr}(\vec{r}) &= (\text{lr}(r_1), \dots, \text{lr}(r_k)), \\ \text{lr}_{\text{inf}}(\vec{r}) &= (\text{lr}_{\text{inf}}(r_1), \dots, \text{lr}_{\text{inf}}(r_k)), \\ \text{lr}_{\text{sup}}(\vec{r}) &= (\text{lr}_{\text{sup}}(r_1), \dots, \text{lr}_{\text{sup}}(r_k)). \end{aligned}$$

Now we introduce the expectation and satisfaction objectives determined by \vec{r} .

- The *expectation* objective amounts to maximizing or minimizing the expected value of $\text{lr}(\vec{r})$. Since $\text{lr}(\vec{r})$ may be undefined for some runs, we actually aim at maximizing

the expected value of $\text{lr}_{\text{inf}}(\vec{r})$ or minimizing the expected value of $\text{lr}_{\text{sup}}(\vec{r})$ (wrt. componentwise ordering \leq).

- The *satisfaction* objective means maximizing the probability of all runs where $\text{lr}(\vec{r})$ stays above or below a given vector \vec{v} . Technically, we aim at maximizing the probability of all runs where $\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}$ or $\text{lr}_{\text{sup}}(\vec{r}) \leq \vec{v}$.

The expectation objective is relevant in situations when we are interested in the average or aggregate behaviour of many instances of a system, and in contrast, the satisfaction objective is relevant when we are interested in particular executions of a system and wish to optimize the probability of generating the desired executions. Since $\text{lr}_{\text{inf}}(\vec{r}) = -\text{lr}_{\text{sup}}(-\vec{r})$, the problems of maximizing and minimizing the expected value of $\text{lr}_{\text{inf}}(\vec{r})$ and $\text{lr}_{\text{sup}}(\vec{r})$ are dual. Therefore, we consider just the problem of maximizing the expected value of $\text{lr}_{\text{inf}}(\vec{r})$. For the same reason, we consider only the problem of maximizing the probability of all runs where $\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}$.

If k (the dimension of \vec{r}) is at least two, there might be several incomparable solutions to the expectation objective; and if \vec{v} is slightly changed, the achievable probability of all runs satisfying $\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}$ may change considerably. Therefore, we aim not only at constructing a particular solution, but on characterizing and approximating the whole space of *achievable solutions* for the expectation/satisfaction objective. Let $s \in S$ be some (initial) state of G . We define the sets $\text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$ and $\text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$ of *achievable vectors* for the expectation and satisfaction objectives as follows:

$$\begin{aligned} \text{AcEx}(\text{lr}_{\text{inf}}(\vec{r})) &= \{\vec{v} \mid \exists \sigma \in \Sigma : \mathbb{E}_s^\sigma[\text{lr}_{\text{inf}}(\vec{r})] \geq \vec{v}\}, \\ \text{AcSt}(\text{lr}_{\text{inf}}(\vec{r})) &= \{(\nu, \vec{v}) \mid \exists \sigma \in \Sigma : \mathbb{P}_s^\sigma[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}] \geq \nu\}. \end{aligned}$$

Intuitively, if \vec{v}, \vec{u} are achievable vectors such that $\vec{v} > \vec{u}$, then \vec{v} represents a “strictly better” solution than \vec{u} . The set of “optimal” solutions defines the *Pareto curve* for $\text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$ and $\text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$. In general, the Pareto curve for a given set $Q \subseteq \mathbb{R}^k$ is the set P of all minimal vectors $\vec{v} \in \mathbb{R}^k$ such $\vec{v} \not\prec \vec{u}$ for all $\vec{u} \in Q$. Note that P may contain vectors that are not in Q (for example, if $Q = \{x \in \mathbb{R} \mid x < 2\}$, then $P = \{2\}$). However, every vector $\vec{v} \in P$ is “almost” in Q in the sense that for every $\varepsilon > 0$ there is $\vec{u} \in Q$ with $\vec{v} \leq \vec{u} + \vec{\varepsilon}$, where $\vec{\varepsilon} = (\varepsilon, \dots, \varepsilon)$. This naturally leads to the notion of an ε -*approximate Pareto curve*, P_ε , which is a subset of Q such that for all vectors $\vec{v} \in P$ of the Pareto curve there is a vector $\vec{u} \in P_\varepsilon$ such that $\vec{v} \leq \vec{u} + \vec{\varepsilon}$. Note that P_ε is not unique.

A running example (II). Consider again the MDP G of Fig. 1a, and the strategy σ constructed in our running example (I). Let $\vec{r} = (r_1, r_2)$, where $r_1(a_6) = 1$, $r_2(a_3) = 2$, $r_2(a_4) = 1$, and otherwise the rewards are zero. Let

$$\omega = (s_1, m_1, a_2)(s_3, m_1, a_5)((s_3, m_2, a_4)(s_4, m_2, a_6))^\omega$$

Then $\text{lr}(\vec{r})(\omega) = (0.5, 0.5)$. Considering the expectation objective, we have that $\mathbb{E}_{s_1}^\sigma[\text{lr}_{\text{inf}}(\vec{r})] = (\frac{3}{52}, \frac{22}{13})$. Considering the satisfaction objective, we have that $(0.5, 0, 2) \in \text{AcSt}(\vec{r})$ because $\mathbb{P}_{s_1}^\sigma[\text{lr}_{\text{inf}}(\vec{r}) \geq (0, 2)] = 0.5$. The Pareto curve for $\text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$ consists of the points $\{(\frac{3}{13}x, \frac{10}{13}x + 2(1-x)) \mid 0 \leq x \leq 0.5\}$, and the Pareto curve for $\text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$ is $\{(1, 0, 2)\} \cup \{(0.5, x, 1-x) \mid 0 < x_1 \leq \frac{10}{13}\}$.

Now we are equipped with all the notions needed for understanding the main results of this paper. Our work is motivated by the six fundamental questions given in Section I. In the next subsections we give detailed answers to these questions.

A. Expectation objectives

The answers to Q.1-Q.6 for the expectation objectives are the following:

- A.1 2-memory stochastic-update strategies are sufficient for all achievable solutions, i.e., for all $\vec{v} \in \text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$ there is a 2-memory stochastic-update strategy σ satisfying $\mathbb{E}_s^\sigma[\text{lr}_{\text{inf}}(\vec{r})] \geq \vec{v}$.
- A.2 The Pareto curve P for $\text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$ is a subset of $\text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$, i.e., all optimal solutions are achievable.
- A.3 There is a polynomial time algorithm which, given $\vec{v} \in \mathbb{Q}^k$, decides whether $\vec{v} \in \text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$.
- A.4 If $\vec{v} \in \text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$, then there is a 2-memory stochastic-update strategy σ constructible in polynomial time satisfying $\mathbb{E}_s^\sigma[\text{lr}_{\text{inf}}(\vec{r})] \geq \vec{v}$.
- A.5 There is a polynomial time algorithm which, given $\vec{v} \in \mathbb{R}^k$, decides whether \vec{v} belongs to the Pareto curve for $\text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$.
- A.6 $\text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$ is a convex hull of finitely many vectors that can be computed in exponential time. The Pareto curve for $\text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$ is a union of all facets of $\text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$ whose vectors are not strictly dominated by vectors of $\text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$. Further, an ε -approximate Pareto curve for $\text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$ is computable in time polynomial in $\frac{1}{\varepsilon}$, $|G|$, and $\max_{a \in A} \max_{1 \leq i \leq k} |\vec{r}_i(a)|$, and exponential in k .

Let us note that A.1 is tight in the sense that neither memoryless randomized nor pure strategies are sufficient for achievable solutions. This is witnessed by the MDP of Fig. 1b with reward functions r_1, r_2 such that $r_i(a_i) = 1$ and $r_i(a_j) = 0$ for $i \neq j$. Consider a strategy σ which initially selects between the actions a_1 and b randomly (with probability 0.5) and then keeps selecting a_1 or a_2 , whichever is available. Hence, $\mathbb{E}_{s_1}^\sigma[\text{lr}_{\text{inf}}((r_1, r_2))] = (0.5, 0.5)$. However, the vector $(0.5, 0.5)$ is not achievable by a strategy σ' which is memoryless or pure, because then we inevitably have that $\mathbb{E}_{s_1}^{\sigma'}[\text{lr}_{\text{inf}}((r_1, r_2))]$ is equal either to $(0, 1)$ or $(1, 0)$.

On the other hand, the 2-memory stochastic-update strategy constructed in the proof of Theorem 1 can be efficiently transformed into a finite-memory deterministic-update randomized strategy, and hence the answers A.1 and A.4 are also valid for *finite-memory deterministic-update randomized* strategies (see Appendix C). Observe that A.2 can be seen as a generalization of the well-known result for single payoff functions which says that finite-state MDPs with mean-payoff objectives have optimal strategies (in this case, the Pareto curve consists of a single number known as the “value”). Also observe that A.2 does *not* hold for infinite-state MDPs (a counterexample is trivial to construct).

Finally, note that if σ is a finite-memory stochastic-update strategy, then G_s^σ is a *finite-state* Markov chain. Hence, for

almost all runs ω in G_s^σ we have that $\text{lr}(\vec{r})(\omega)$ exists and it is equal to $\text{lr}_{\text{inf}}(\vec{r})(\omega)$. This means that there is actually no difference between maximizing the expected value of $\text{lr}_{\text{inf}}(\vec{r})$ and the expected value of $\text{lr}(\vec{r})$.

B. Satisfaction objectives

The answers to Q.1-Q.6 for the satisfaction objectives are presented below.

B.1 Achievable vectors require strategies with infinite memory in general. However, memoryless randomized strategies are sufficient for ε -approximate achievable vectors, i.e., for every $\varepsilon > 0$ and $(\nu, \vec{v}) \in \text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$, there is a memoryless randomized strategy σ with

$$\mathbb{P}_s^\sigma[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v} - \vec{\varepsilon}] \geq \nu - \varepsilon.$$

Here $\vec{\varepsilon} = (\varepsilon, \dots, \varepsilon)$.

B.2 The Pareto curve P for $\text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$ is a subset of $\text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$, i.e., all optimal solutions are achievable.

B.3 There is a polynomial time algorithm which, given $\nu \in [0, 1]$ and $\vec{v} \in \mathbb{Q}^k$, decides whether $(\nu, \vec{v}) \in \text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$.

B.4 If $(\nu, \vec{v}) \in \text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$, then for every $\varepsilon > 0$ there is a memoryless randomized strategy σ constructible in polynomial time such that $\mathbb{P}_s^\sigma[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v} - \vec{\varepsilon}] \geq \nu - \varepsilon$.

B.5 There is a polynomial time algorithm which, given $\nu \in [0, 1]$ and $\vec{v} \in \mathbb{R}^k$, decides whether (ν, \vec{v}) belongs to the Pareto curve for $\text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$.

B.6 The Pareto curve P for $\text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$ may be neither connected, nor closed. However, P is a union of finitely many sets whose closures are convex polytopes, and, perhaps surprisingly, the set $\{\nu \mid (\nu, \vec{v}) \in P\}$ is always finite. The sets in the union that gives P (resp. the inequalities that define them) can be computed. Further, an ε -approximate Pareto curve for $\text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$ is computable in time polynomial in $\frac{1}{\varepsilon}$, $|G|$, and $\max_{a \in A} \max_{1 \leq i \leq k} |\vec{r}_i(a)|$, and exponential in k .

The algorithms of B.3 and B.4 are polynomial in the size of G and the size of binary representations of \vec{v} and $\frac{1}{\varepsilon}$.

The result B.1 is again tight. In Appendix D we show that memoryless pure strategies are insufficient for ε -approximate achievable vectors, i.e., there are $\varepsilon > 0$ and $(\nu, \vec{v}) \in \text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$ such that for every memoryless pure strategy σ we have that $\mathbb{P}_s^\sigma[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v} - \vec{\varepsilon}] < \nu - \varepsilon$.

As noted in B.1, a strategy σ achieving a given vector $(\nu, \vec{v}) \in \text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$ may require infinite memory. Still, our proof of B.1 reveals a “recipe” for constructing such a σ by simulating the memoryless randomized strategies σ_ε which ε -approximate (ν, \vec{v}) (intuitively, for smaller and smaller ε , the strategy σ simulates σ_ε longer and longer; the details are discussed in Section V). Hence, for almost all runs ω in G_s^σ we again have that $\text{lr}(\vec{r})(\omega)$ exists and it is equal to $\text{lr}_{\text{inf}}(\vec{r})(\omega)$.

IV. PROOFS FOR EXPECTATION OBJECTIVES

The technical core of our results for expectation objectives is the following:

Theorem 1: Let $G = (S, A, \text{Act}, \delta)$ be a MDP, $\vec{r} = (r_1, \dots, r_k)$ a tuple of reward functions, and $\vec{v} \in \mathbb{R}^k$. Then

$$\mathbf{1}_{s_0}(s) + \sum_{a \in A} y_a \cdot \delta(a)(s) = \sum_{a \in \text{Act}(s)} y_a + y_s \quad \text{for all } s \in S \quad (1)$$

$$\sum_{s \in S} y_s = 1 \quad (2)$$

$$\sum_{s \in C} y_s = \sum_{a \in A \cap C} x_a \quad \text{for all MEC } C \text{ of } G \quad (3)$$

$$\sum_{a \in A} x_a \cdot \delta(a)(s) = \sum_{a \in \text{Act}(s)} x_a \quad \text{for all } s \in S \quad (4)$$

$$\sum_{a \in A} x_a \cdot \vec{r}_i(a) \geq \vec{v}_i \quad \text{for all } 1 \leq i \leq n \quad (5)$$

Fig. 2: System L of linear inequalities. (We define $\mathbf{1}_{s_0}(s) = 1$ if $s = s_0$, and $\mathbf{1}_{s_0}(s) = 0$ otherwise.)

there exists a system of linear inequalities L constructible in polynomial time such that

- every nonnegative solution of L induces a 2-memory stochastic-update strategy σ satisfying $\mathbb{E}_{s_0}^\sigma[\text{lr}_{\text{inf}}(\vec{r})] \geq \vec{v}$;
- if $\vec{v} \in \text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$, then L has a nonnegative solution.

As we already noted in Section I, the proof of Theorem 1 is non-trivial and it is based on novel techniques and observations. Our results about expectation objectives are corollaries to Theorem 1 and the arguments developed in its proof. For the rest of this section, we fix an MDP G , a vector of rewards, $\vec{r} = (r_1, \dots, r_k)$, and an initial state s_0 (in the considered plays of G , the initial state is not written explicitly, unless it is different from s_0).

Consider the system L of Fig. 2 (parametrized by \vec{v}). Obviously, L is constructible in polynomial time. Probably most demanding are Eqns. (1) and Eqns. (4). The equations of (1) are analogous to similar equalities in [6], and their purpose is clarified at the end of the proof of Proposition 2. The meaning of Eqns. (4) is explained in Lemma 1.

As both directions of Theorem 1 are technically involved, we prove them separately as Propositions 1 and 2.

Proposition 1: Every nonnegative solution of the system L induces a 2-memory stochastic-update strategy σ satisfying $\mathbb{E}_{s_0}^\sigma[\text{lr}_{\text{inf}}(\vec{r})] \geq \vec{v}$.

Proof of Proposition 1: First, let us consider Eqn. (4) of L . Intuitively, this equation is solved by an “invariant” distribution on actions, i.e., each solution gives frequencies of actions (up to a multiplicative constant) defined for all $a \in A$, $s \in S$, and $\sigma \in \Sigma$ by

$$\text{freq}(\sigma, s, a) := \lim_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T \mathbb{P}_s^\sigma[A_t = a],$$

assuming that the defining limit exists (which might not be the case—cf. the proof of Proposition 2). We prove the following:

Lemma 1: Assume that assigning (nonnegative) values \bar{x}_a to x_a solves Eqn. (4). Then there is a memoryless strategy ξ such that for every BSCCs D of G^ξ , every $s \in D \cap S$, and every $a \in D \cap A$, we have that $\text{freq}(\xi, s, a)$ equals a common value $\text{freq}(\xi, D, a) := \bar{x}_a / \sum_{a' \in D \cap A} \bar{x}_{a'}$.

A proof of Lemma 1 is given in Appendix A. Assume that the system L is solved by assigning nonnegative values

\bar{x}_a to x_a and \bar{y}_χ to y_χ where $\chi \in A \cup S$. Let ξ be the strategy of Lemma 1. Using Eqns. (1), (2), and (3), we will define a 2-memory stochastic update strategy σ as follows. The strategy σ has two memory elements, m_1 and m_2 . A run of G^σ starts in s_0 with a given distribution on memory elements (see below). Then σ plays according to a suitable memoryless strategy (constructed below) until the memory changes to m_2 , and then it starts behaving as ξ forever. Given a BSCC D of G^ξ , we denote by $\mathbb{P}_{s_0}^\sigma[\text{switch to } \xi \text{ in } D]$ the probability that σ switches from m_1 to m_2 while in D . We construct σ so that

$$\mathbb{P}_{s_0}^\sigma[\text{switch to } \xi \text{ in } D] = \sum_{a \in D \cap A} \bar{x}_a. \quad (6)$$

Then $\text{freq}(\sigma, s_0, a) = \mathbb{P}_{s_0}^\sigma[\text{switch to } \xi \text{ in } D] \cdot \text{freq}(\xi, D, a) = \bar{x}_a$. Finally, we obtain the following:

$$\mathbb{E}_{s_0}^\sigma[\text{lr}_{\text{inf}}(\bar{r}_i)] = \sum_{a \in A} \bar{r}_i(a) \cdot \bar{x}_a. \quad (7)$$

A complete derivation of Eqn. (7) is given in Appendix A2. Note that the right-hand side of Eqn. (7) is greater than or equal to \bar{v}_i by Inequality (5) of L .

So, it remains to construct the strategy σ with the desired “switching” property expressed by Eqn. (6). Roughly speaking, we proceed in two steps.

1. We construct a *finite-memory* stochastic update strategy $\bar{\sigma}$ satisfying Eqn. (6). The strategy $\bar{\sigma}$ is constructed so that it initially behaves as a certain finite-memory stochastic update strategy, but eventually this mode is “switched” to the strategy ξ which is followed forever.
2. The only problem with $\bar{\sigma}$ is that it may use more than two memory elements in general. This is solved by applying the results of [6] and reducing the “initial part” of $\bar{\sigma}$ (i.e., the part before the switch) into a *memoryless* strategy. Thus, we transform $\bar{\sigma}$ into an “equivalent” strategy σ which is 2-memory stochastic update.

Now we elaborate the two steps.

Step 1. For every MEC C of G , we denote by y_C the number $\sum_{s \in C} \bar{y}_s = \sum_{a \in A \cap C} \bar{x}_a$. By combining the solution of L with the results of Sections 3 and 5 of [6] (the details are given in Appendix A, Lemma 2), one can construct a finite-memory stochastic-update strategy ζ which stays eventually in each MEC C with probability y_C .

The strategy $\bar{\sigma}$ works as follows. For a run initiated in s_0 , the strategy $\bar{\sigma}$ plays according to ζ until a BSCC of G^ζ is reached. This means that every possible continuation of the path stays in the current MEC C of G . Assume that C has states s_1, \dots, s_k . We denote by \bar{x}_s the sum $\sum_{a \in \text{Act}(s)} \bar{x}_a$. At this point, the strategy $\bar{\sigma}$ changes its behavior as follows: First, the strategy $\bar{\sigma}$ strives to reach s_1 with probability one. Upon reaching s_1 , it chooses (randomly, with probability $\frac{\bar{x}_{s_1}}{y_C}$) either to behave as ξ forever, or to follow on to s_2 . If the strategy $\bar{\sigma}$ chooses to go on to s_2 , it strives to reach s_2 with probability one. Upon reaching s_2 , the strategy $\bar{\sigma}$ chooses (randomly, with probability $\frac{\bar{x}_{s_2}}{y_C - \bar{x}_{s_1}}$) either to behave as ξ forever, or to follow on to s_3 , and so, till s_k . That is, the probability of switching to ξ in s_i is $\frac{\bar{x}_{s_i}}{y_C - \sum_{j=1}^{i-1} \bar{x}_{s_j}}$.

Since ζ stays in a MEC C with probability y_C , the probability that the strategy $\bar{\sigma}$ switches to ξ in s_i is equal to \bar{x}_{s_i} . However, then for every BSCC D of G^ζ satisfying $D \cap C \neq \emptyset$ (and thus $D \subseteq C$) we have that the strategy $\bar{\sigma}$ switches to ξ in a state of D with probability $\sum_{s \in D \cap S} \bar{x}_s = \sum_{a \in D \cap A} \bar{x}_a$. Hence, $\bar{\sigma}$ satisfies Eqn. (6).

Step 2. Now we show how to reduce the first phase of $\bar{\sigma}$ (before the switch to ξ) into a memoryless strategy, using the results of [6, Section 3]. Unfortunately, these results are not applicable directly. We need to modify the MDP G into a new MDP G' as follows: For each state s we add a new absorbing state, d_s . The only available action for d_s leads to a loop transition back to d_s with probability 1. We also add a new action, a_s^d , to every $s \in S$. The distribution associated with a_s^d assigns probability 1 to d_s .

Let us consider a finite-memory stochastic-update strategy, σ' , for G' defined as follows. The strategy σ' behaves as $\bar{\sigma}$ before the switch to ξ . Once $\bar{\sigma}$ switches to ξ , say in a state s of G with probability p_s , the strategy σ' chooses the action a_s^d with probability p_s . It follows that the probability of $\bar{\sigma}$ switching in s is equal to the probability of reaching d_s in G' under σ' . By [6, Theorem 3.2], there is a memoryless strategy, σ'' , for G' that reaches d_s with probability p_s . We define σ in G to behave as σ'' with the exception that, in every state s , instead of choosing an action a_s^d with probability p_s it switches to behave as ξ with probability p_s (which also means that the initial distribution on memory elements assigns p_{s_0} to m_2). Then, clearly, σ satisfies Eqn. (6) because

$$\begin{aligned} \mathbb{P}_{s_0}^\sigma[\text{switch in } D] &= \sum_{s \in D} \mathbb{P}_{s_0}^{\sigma''}[\text{fire } a_s^d] = \sum_{s \in D} \mathbb{P}_{s_0}^{\sigma'}[\text{fire } a_s^d] \\ &= \mathbb{P}_{s_0}^{\bar{\sigma}}[\text{switch in } D] = \sum_{a \in D \cap A} \bar{x}_a. \end{aligned}$$

This concludes the proof of Proposition 1. \blacksquare

Proposition 2: If $\bar{v} \in \text{AcEx}(\text{lr}_{\text{inf}}(\bar{r}))$, then L has a nonnegative solution.

Proof of Proposition 2: Let $\varrho \in \Sigma$ be a strategy such that $\mathbb{E}_{s_0}^\varrho[\text{lr}_{\text{inf}}(\bar{r})] \geq \bar{v}$. In general, the frequencies $\text{freq}(\varrho, s_0, a)$ of the actions may not be well defined, because the defining limits may not exist. A crucial trick to overcome this difficulty is to pick suitable “related” values, $f(a)$, lying between $\liminf_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T \mathbb{P}_{s_0}^\varrho[A_t = a]$ and $\limsup_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T \mathbb{P}_{s_0}^\varrho[A_t = a]$, which can be safely substituted for x_a in L . Since every infinite sequence contains an infinite convergent subsequence, there is an increasing sequence of indices, T_0, T_1, \dots , such that the following limit exists for each action $a \in A$

$$f(a) := \lim_{\ell \rightarrow \infty} \frac{1}{T_\ell} \sum_{t=1}^{T_\ell} \mathbb{P}_{s_0}^\varrho[A_t = a].$$

Setting $x_a := f(a)$ for all $a \in A$ satisfies Inqs. (5) and Eqns. (4) of L . Indeed, the former follows from $\mathbb{E}_{s_0}^\varrho[\text{lr}_{\text{inf}}(\bar{r})] \geq \bar{v}$ and the following inequality, which holds for all $1 \leq i \leq k$:

$$\sum_{a \in A} \bar{r}_i(a) \cdot f(a) \geq \mathbb{E}_{s_0}^\varrho[\text{lr}_{\text{inf}}(\bar{r}_i)]. \quad (8)$$

A proof of Inequality (8) is given in Appendix A3. To prove that Eqns. (4) are satisfied, it suffices to show that for all $s \in S$ we have

$$\sum_{a \in A} f(a) \cdot \delta(a)(s) = \sum_{a \in \text{Act}(s)} f(a). \quad (9)$$

A proof of Eqn. (9) is given in Appendix A4.

Now we have to set the values for y_χ , $\chi \in A \cup S$, and prove that they satisfy the rest of L when the values $f(a)$ are assigned to x_a . Note that every run of G^ϱ eventually stays in some MEC of G (cf., e.g., [5, Proposition 3.1]). For every MEC C of G , let y_C be the probability of all runs in G^ϱ that eventually stay in C . Note that

$$\begin{aligned} \sum_{a \in A \cap C} f(a) &= \sum_{a \in A \cap C} \lim_{\ell \rightarrow \infty} \frac{1}{T_\ell} \sum_{t=1}^{T_\ell} \mathbb{P}_{s_0}^\varrho[A_t = a] \\ &= \lim_{\ell \rightarrow \infty} \frac{1}{T_\ell} \sum_{t=1}^{T_\ell} \sum_{a \in A \cap C} \mathbb{P}_{s_0}^\varrho[A_t = a] \\ &= \lim_{\ell \rightarrow \infty} \frac{1}{T_\ell} \sum_{t=1}^{T_\ell} \mathbb{P}_{s_0}^\varrho[A_t \in C] = y_C. \end{aligned} \quad (10)$$

Here the last equality follows from the fact that $\lim_{\ell \rightarrow \infty} \mathbb{P}_{s_0}^\varrho[A_{T_\ell} \in C]$ is equal to the probability of all runs in G^ϱ that eventually stay in C (recall that almost every run stays eventually in a MEC of G) and the fact that the Cesàro sum of a convergent sequence is equal to the limit of the sequence.

To obtain y_a and y_s , we need to simplify the behavior of ϱ before reaching a MEC for which we use the results of [6]. As in the proof of Proposition 1, we first need to modify the MDP G into another MDP G' as follows: For each state s we add a new absorbing state, d_s . The only available action for d_s leads to a loop transition back to d_s with probability 1. We also add a new action, a_s^d , to every $s \in S$. The distribution associated with a_s^d assigns probability 1 to d_s . By [6, Theorem 3.2], the existence of ϱ implies the existence of a memoryless pure strategy ζ for G' such that

$$\sum_{s \in C} \mathbb{P}_{s_0}^\zeta[\text{Reach}(d_s)] = y_C. \quad (11)$$

Let U_a be a function over the runs in G' returning the (possibly infinite) number of times the action a is used. We are now ready to define the assignment for the variables y_χ of L .

$$\begin{aligned} y_a &:= \mathbb{E}_{s_0}^\zeta[U_a] && \text{for all } a \in A \\ y_s &:= \mathbb{E}_{s_0}^\zeta[U_{a_s^d}] = \mathbb{P}_{s_0}^\zeta[\text{Reach}(d_s)] && \text{for all } s \in S. \end{aligned}$$

Note that [6, Lemma 3.3] ensures that all y_a and y_s are indeed well-defined finite values, and satisfy Eqns. (1) of L . Eqns. (3) of L are satisfied due to Eqns. (11) and (10). Eqn. (11) together with $\sum_{a \in A} f(a) = 1$ imply Eqn. (2) of L . This completes the proof of Proposition 2. ■

The item A.1 in Section III-A follows directly from Theorem 1. Let us analyze A.2. Suppose \vec{v} is a point of the Pareto curve. Consider the system L' of linear inequalities obtained from L by replacing constants \vec{v}_i in Inqs. (5) with new variables z_i . Let $Q \subseteq \mathbb{R}^n$ be the projection of the set

of solutions of L' to z_1, \dots, z_n . From Theorem 1 and the definition of Pareto curve, the (Euclid) distance of \vec{v} to Q is 0. Because the set of solutions of L' is a closed set, Q is also closed and thus $\vec{v} \in Q$. This gives us a solution to L with variables z_i having values \vec{v}_i , and we can use Theorem 1 to get a strategy witnessing that $\vec{v} \in \text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$.

Now consider the items A.3 and A.4. The system L is linear, and hence the problem whether $\vec{v} \in \text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$ is decidable in polynomial time by employing polynomial time algorithms for linear programming. A 2-memory stochastic-update strategy σ satisfying $\mathbb{E}_s^\sigma[\text{lr}_{\text{inf}}(\vec{r})] \geq \vec{v}$ can be computed as follows (note that the proof of Proposition 1 is *not* fully constructive, so we cannot apply this proposition immediately). First, we find a solution of the system L , and we denote by \bar{x}_a the value assigned to x_a . Let $(T_1, B_1), \dots, (T_n, B_n)$ be the end components such that $a \in \bigcup_{i=1}^n B_i$ iff $\bar{x}_a > 0$, and T_1, \dots, T_n are pairwise disjoint. We construct another system of linear inequalities consisting of Eqns. (1) of L and the equations $\sum_{s \in T_i} y_s = \sum_{s \in T_i} \sum_{a \in \text{Act}(s)} \bar{x}_a$ for all $1 \leq i \leq n$. Due to [6], there is a solution to this system iff in the MDP G' from the proof of Proposition 1 there is a strategy that for every i reaches d_s for $s \in T_i$ with probability $\sum_{s \in T_i} \sum_{a \in \text{Act}(s)} \bar{x}_a$. Such a strategy indeed exists (consider, e.g., the strategy σ' from the proof of Proposition 1). Thus, there is a solution to the above system and we can denote by \hat{y}_s and \hat{y}_a the values assigned to y_s and y_a . We define σ by

$$\begin{aligned} \sigma_n(s, m_1)(a) &= \hat{y}_a / \sum_{a' \in \text{Act}(s)} \hat{y}_{a'} \\ \sigma_n(s, m_2)(a) &= \bar{x}_a / \sum_{a' \in \text{Act}(s)} \bar{x}_{a'} \end{aligned}$$

and further $\sigma_u(a, s, m_1)(m_2) = y_s$, $\sigma_u(a, s, m_2)(m_2) = 1$, and the initial memory distribution assigns $(1 - y_{s_0})$ and y_{s_0} to m_1 and m_2 , respectively. Due to [6] we have $\mathbb{P}_{s_0}^\sigma[\text{change memory to } m_2 \text{ in } s] = \hat{y}_s$, and the rest follows similarly as in the proof of Proposition 1.

The item A.5 can be proved as follows: To test that $\vec{v} \in \text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$ lies in the Pareto curve we turn the system L into a linear program LP by adding the objective to maximize $\sum_{1 \leq i \leq n} \sum_{a \in A} x_a \cdot \vec{r}_i(a)$. Then we check that there is no better solution than $\sum_{1 \leq i \leq n} \vec{v}_i$.

Finally, the item A.6 is obtained by considering the system L' above and computing all exponentially many vertices of the polytope of all solutions. Then we compute projections of these vertices onto the dimensions z_1, \dots, z_n and retrieve all the maximal vertices. Moreover, if for every $\vec{v} \in \{\ell \cdot \varepsilon \mid \ell \in \mathbb{Z} \wedge -M_r \leq \ell \cdot \varepsilon \leq M_r\}^k$ where $M_r = \max_{a \in A} \max_{1 \leq i \leq k} |\vec{r}_i(a)|$ we decide whether $\vec{v} \in \text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$, we can easily construct an ε -approximate Pareto curve.

V. PROOFS FOR SATISFACTION OBJECTIVES

In this section we prove the items B.1–B.6 of Section III-B. Let us fix a MDP G , a vector of rewards, $\vec{r} = (r_1, \dots, r_k)$, and an initial state s_0 . We start by assuming that the MDP G is strongly connected (i.e., (S, A) is an end component).

Proposition 3: Assume that G is strongly connected and that there is a strategy π such that $\mathbb{P}_{s_0}^\pi[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}] > 0$. Then the following is true.

1. There is a strategy ξ satisfying $\mathbb{P}_s^\xi[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}] = 1$ for all $s \in S$.
2. For each $\varepsilon > 0$ there is a memoryless randomized strategy ξ_ε satisfying $\mathbb{P}_s^{\xi_\varepsilon}[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v} - \vec{\varepsilon}] = 1$ for all $s \in S$.

Moreover, the problem whether there is some π such that $\mathbb{P}_{s_0}^\pi[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}] > 0$ is decidable in polynomial time. Strategies ξ_ε are computable in time polynomial in the size of G , the size of the binary representation of \vec{r} , and $\frac{1}{\varepsilon}$.

Proof: By [2], [9], $\mathbb{P}_{s_0}^\pi[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}] > 0$ implies that there is a strategy ξ such that $\mathbb{P}_{s_0}^\xi[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}] = 1$ (the details are given in Appendix B). This gives us item 1. of Proposition 3 and also immediately implies $\vec{v} \in \text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$. It follows that there are nonnegative values \bar{x}_a for all $a \in A$ such that assigning \bar{x}_a to x_a solves Eqns. (4) and (5) of the system L (see Fig. 2). Let us assume, w.l.o.g., that $\sum_{a \in A} \bar{x}_a = 1$.

Lemma 1 gives us a memoryless randomized strategy ζ such that for all BSCCs D of G^ζ , all $s \in D \cap S$ and all $a \in D \cap A$ we have that $\text{freq}(\zeta, s, a) = \frac{\bar{x}_a}{\sum_{a \in D \cap A} \bar{x}_a}$. We denote by $\text{freq}(\zeta, D, a)$ the value $\frac{\bar{x}_a}{\sum_{a \in D \cap A} \bar{x}_a}$.

Now we are ready to prove the item 2 of Proposition 3. Let us fix $\varepsilon > 0$. We obtain ξ_ε by a suitable perturbation of the strategy ζ in such a way that all actions get positive probabilities and the frequencies of actions change only slightly. There exists an arbitrarily small (strictly) positive solution x'_a of Eqns. (4) of the system L (it suffices to consider a strategy τ which always takes the uniform distribution over the actions in every state and then assign $\text{freq}(\tau, s_0, a)/N$ to x_a for sufficiently large N). As the system of Eqns. (4) is linear and homogeneous, assigning $\bar{x}_a + x'_a$ to x_a also solves this system and Lemma 1 gives us a strategy ξ_ε satisfying $\text{freq}(\xi_\varepsilon, s_0, a) = (\bar{x}_a + x'_a)/X$. Here $X = \sum_{a' \in A} \bar{x}_{a'} + x'_{a'} = 1 + \sum_{a' \in A} x'_{a'}$. We may safely assume that $\sum_{a' \in A} x'_{a'} \leq \frac{\varepsilon}{2M_r}$ where $M_r = \max_{a \in A} \max_{1 \leq i \leq k} |\vec{r}_i(a)|$. Thus, we obtain

$$\sum_{a \in A} \text{freq}(\xi_\varepsilon, s_0, a) \cdot \vec{r}_i(a) \geq \vec{v}_i - \varepsilon. \quad (12)$$

A proof of Inequality (12) is given in Appendix B1. As G^{ξ_ε} is strongly connected, almost all runs ω of G^{ξ_ε} initiated in s_0 satisfy

$$\text{lr}_{\text{inf}}(\vec{r})(\omega) = \sum_{a \in A} \text{freq}(\xi_\varepsilon, s_0, a) \cdot \vec{r}(a) \geq \vec{v} - \vec{\varepsilon}.$$

This finishes the proof of item 2.

Concerning the complexity of computing ξ_ε , note that the binary representation of every coefficient in L has only polynomial length. As \bar{x}_a 's are obtained as a solution of (a part of) L , standard results from linear programming imply that each \bar{x}_a has a binary representation computable in polynomial time. The numbers x'_a are also obtained by solving a part of L and restricted by $|\sum_{a' \in A} x'_{a'}| \leq \frac{\varepsilon}{2M_r}$ which allows to compute a binary representation of x'_a in polynomial time. The strategy ξ_ε , defined in the proof of Proposition 3, assigns to each action only small arithmetic expressions over \bar{x}_a and x'_a . Hence, ξ_ε is computable in polynomial time.

To prove that the problem whether there is some ξ such that $\mathbb{P}_{s_0}^\xi[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}] > 0$ is decidable in polynomial time,

we show that whenever $\vec{v} \in \text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$, then $(1, \vec{v}) \in \text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$. This gives us a polynomial time algorithm by applying Theorem 1. Let $\vec{v} \in \text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$. We show that there is a strategy ξ such that $\mathbb{P}_s^\xi[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}] = 1$. The strategy σ needs infinite memory (an example demonstrating that infinite memory is required is given in Appendix D).

Since $\vec{v} \in \text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$, there are nonnegative rational values \bar{x}_a for all $a \in A$ such that assigning \bar{x}_a to x_a solves Eqns. (4) and (5) of the system L . Assume, without loss of generality, that $\sum_{a \in A} \bar{x}_a = 1$.

Given $a \in A$, let $I_a : A \rightarrow \{0, 1\}$ be a function given by $I_a(a) = 1$ and $I_a(b) = 0$ for all $b \neq a$. For every $i \in \mathbb{N}$, we denote by ξ_i a memoryless randomized strategy satisfying $\mathbb{P}_s^{\xi_i}[\text{lr}_{\text{inf}}(I_a) \geq \bar{x}_a - 2^{-i-1}] = 1$. Note that for every $i \in \mathbb{N}$ there is $\kappa_i \in \mathbb{N}$ such that for all $a \in A$ and $s \in S$ we get

$$\mathbb{P}_s^{\xi_i} \left[\inf_{T \geq \kappa_i} \frac{1}{T} \sum_{t=0}^T I_a(A_t) \geq \bar{x}_a - 2^{-i} \right] \geq 1 - 2^{-i}.$$

Now let us consider a sequence n_0, n_1, \dots of numbers where $n_i \geq \kappa_i$ and $\frac{\sum_{j < i} n_j}{n_i} \leq 2^{-i}$ and $\frac{\kappa_{i+1}}{n_i} \leq 2^{-i}$. We define ξ to behave as ξ_1 for the first n_1 steps, then as ξ_2 for the next n_2 steps, then as ξ_3 for the next n_3 steps, etc. In general, denoting by N_i the sum $\sum_{j < i} n_j$, the strategy ξ behaves as ξ_i between the N_i 'th step (inclusive) and N_{i+1} 'th step (non-inclusive).

Let us give some intuition behind ξ . The numbers in the sequence n_0, n_1, \dots grow rapidly so that after ξ_i is simulated for n_i steps, the part of the history when ξ_j for $j < i$ were simulated becomes relatively small and has only minor impact on the current average reward (this is ensured by the condition $\frac{\sum_{j < i} n_j}{n_i} \leq 2^{-i}$). This gives us that almost every run has infinitely many prefixes on which the average reward w.r.t. I_a is arbitrarily close to \bar{x}_a infinitely often. To get that \bar{x}_a is also the limit average reward, one only needs to be careful when the strategy ξ ends behaving as ξ_i and starts behaving as ξ_{i+1} , because then up to the κ_{i+1} steps we have no guarantee that the average reward is close to \bar{x}_a . This part is taken care of by picking n_i so large that the contribution (to the average reward) of the n_i steps according to ξ_i prevails over fluctuations introduced by the first κ_{i+1} steps according to ξ_{i+1} (this is ensured by the condition $\frac{\kappa_{i+1}}{n_i} \leq 2^{-i}$).

Let us now prove the correctness of the definition of ξ formally. We prove that almost all runs ω of G^ξ satisfy

$$\liminf_{T \rightarrow \infty} \frac{1}{T} \sum_{t=0}^T I_a(A_t(\omega)) \geq \bar{x}_a.$$

Denote by E_i the set of all runs $\omega = s_0 a_0 s_1 a_1 \dots$ of G^ξ such that for some $\kappa_i \leq d \leq n_i$ we have

$$\frac{1}{d} \sum_{j=N_i}^{N_i+d} I_a(a_j) < \bar{x}_a - 2^{-i}.$$

We have $\mathbb{P}_{s_0}^\xi[E_i] \leq 2^{-i}$ and thus $\sum_{i=1}^\infty \mathbb{P}_{s_0}^\xi[E_i] = \frac{1}{2} < \infty$. By Borel-Cantelli lemma [15], almost surely only finitely many of E_i take place. Thus, almost every run $\omega = s_0 a_0 s_1 a_1 \dots$ of

G^ξ satisfies the following: there is ℓ such that for all $i \geq \ell$ and all $\kappa_i \leq d \leq n_i$ we have that

$$\frac{1}{d} \sum_{j=N_i}^{N_i+d} I_a(a_j) \geq \bar{x}_a - 2^{-i}.$$

Consider $T \in \mathbb{N}$ such that $N_i \leq T < N_{i+1}$ where $i > \ell$. We prove the following (see Appendix B2):

$$\frac{1}{T} \sum_{t=0}^T I_a(a_t) \geq (\bar{x}_a - 2^{-i})(1 - 2^{1-i}). \quad (13)$$

Since the above sum converges to \bar{x}_a as i (and thus also T) goes to ∞ , we obtain

$$\liminf_{T \rightarrow \infty} \frac{1}{T} \sum_{t=0}^T I_a(a_t) \geq \bar{x}_a. \quad \blacksquare$$

We are now ready to prove the items B.1, B.3 and B.4. Let C_1, \dots, C_ℓ be all MECs of G . We say that a MEC C_i is *good* for \vec{v} if there is a state s of C_i and a strategy π satisfying $\mathbb{P}_s^\pi[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}] > 0$ that never leaves C_i when starting in s . Using Proposition 3, we can decide in polynomial time whether a given MEC is good for a given \vec{v} . Let \mathcal{C} be the union of all MECs good for \vec{v} . Then, by Proposition 3, there is a strategy ξ such that for all $s \in \mathcal{C}$ we have $\mathbb{P}_s^\xi[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}] = 1$ and for each $\varepsilon > 0$ there is a memoryless randomized strategy ξ_ε , computable in polynomial time, such that for all $s \in \mathcal{C}$ we have $\mathbb{P}_{s_0}^{\xi_\varepsilon}[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v} - \varepsilon] = 1$.

Consider a strategy τ , computable in polynomial time, which maximizes the probability of reaching \mathcal{C} . Denote by σ a strategy which behaves as τ before reaching \mathcal{C} and as ξ afterwards. Similarly, denote by σ_ε a strategy which behaves as τ before reaching \mathcal{C} and as ξ_ε afterwards. Note that σ_ε is computable in polynomial time.

Clearly, $(\nu, \vec{v}) \in \text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$ iff $\mathbb{P}_{s_0}^\tau[\text{Reach}(\mathcal{C})] \geq \nu$ because σ achieves \vec{v} with probability $\mathbb{P}_{s_0}^\tau[\text{Reach}(\mathcal{C})]$. Thus, we obtain that $\nu \leq \mathbb{P}_{s_0}^\tau[\text{Reach}(\mathcal{C})] \leq \mathbb{P}_{s_0}^{\xi_\varepsilon}[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v} - \varepsilon]$.

Finally, to decide whether $(\nu, \vec{v}) \in \text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$, it suffices to decide whether $\mathbb{P}_{s_0}^\tau[\text{Reach}(\mathcal{C})] \geq \nu$ in polynomial time.

Now we prove item B.2. Suppose (ν, \vec{v}) is a vector of the Pareto curve. We let \mathcal{C} be the union of all MECs good for \vec{v} . Recall that the Pareto curve constructed for expectation objectives is achievable (item A.2). Due to the correspondence between AcSt and AcEx in strongly connected MDPs we obtain the following. There is $\lambda > 0$ such that for every MEC D not contained in \mathcal{C} , every $s \in D$, and every strategy σ that does not leave D , it is possible to have $\mathbb{P}_s^\sigma[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{u}] > 0$ only if there is i such that $\vec{v}_i - \vec{u}_i \geq \lambda$, i.e., when \vec{v} is greater than \vec{u} by λ in some component. Thus, for every $\varepsilon < \lambda$ and every strategy σ such that $\mathbb{P}_{s_0}^\sigma[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v} - \varepsilon] \geq \nu - \varepsilon$ it must be the case that $\mathbb{P}_{s_0}^\sigma[\text{Reach}(\mathcal{C})] \geq \nu - \varepsilon$. Because for single objective reachability the optimal strategies exist, we get that there is a strategy τ satisfying $\mathbb{P}_{s_0}^\tau[\text{Reach}(\mathcal{C})] \geq \nu$, and by using methods similar to the ones of the previous paragraphs we obtain $(\nu, \vec{v}) \in \text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$.

The polynomial-time algorithm mentioned in item B.5 works as follows. First check whether $(\nu, \vec{v}) \in \text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$

and if not, return “no”. Otherwise, find all MECs good for \vec{v} and compute the maximal probability of reaching them from the initial state. If the probability is *strictly* greater than ν , return “no”. Otherwise, continue by performing the following procedure for every $1 \leq i \leq k$, where k is the dimension of \vec{v} : Find all MECs C for which there is $\varepsilon > 0$ such that C is good for \vec{u} , where \vec{u} is obtained from \vec{v} by increasing the i -th component by ε (this can be done in polynomial time using linear programming). Compute the maximal probability of reaching these MECs. If for any i the probability is *at least* ν , return “no”, otherwise return “yes”.

The first claim of B.6 follows from Running example (II). The other claims of item B.6 require further observations and they are proved in Appendix F.

A. Proofs of Section IV

1) *Proof of Lemma 1:* For all $s \in S$ we set $\bar{x}_s = \sum_{b \in \text{Act}(s)} \bar{x}_b$ and define ξ by $\xi(s)(a) := \frac{\bar{x}_a}{\bar{x}_s}$ if $\bar{x}_s > 0$, and arbitrarily otherwise. We claim that the vector of values \bar{x}_s forms an invariant measure of G^ξ . Indeed, noting that $\sum_{a \in \text{Act}(s)} \xi(s)(a) \cdot \delta(a)(s')$ is the probability of the transition $s \rightarrow s'$ in G^ξ :

$$\begin{aligned} & \sum_{s \in S} \bar{x}_s \cdot \sum_{a \in \text{Act}(s)} \xi(s)(a) \cdot \delta(a)(s') \\ &= \sum_{s \in S} \sum_{a \in \text{Act}(s)} \bar{x}_s \cdot \frac{\bar{x}_a}{\bar{x}_s} \cdot \delta(a)(s') \\ &= \sum_{a \in A} \bar{x}_a \cdot \delta(a)(s') = \sum_{a \in \text{Act}(s')} \bar{x}_a = \bar{x}_{s'}. \end{aligned}$$

As a consequence, $\bar{x}_s > 0$ iff s lies in some BSCC of G^ξ . Choose some BSCC D , and denote by \bar{x}_D the number $\sum_{a \in D \cap A} \bar{x}_a = \sum_{s \in D \cap S} \bar{x}_s$. Also denote by I_t^a the indicator of $A_t = a$, given by $I_t^a = 1$ if $A_t = a$ and 0 otherwise. By the Ergodic theorem for finite Markov chains (see, e.g. [11, Theorem 1.10.2]), for all $s \in D \cap S$ and $a \in D \cap A$ we have

$$\mathbb{E}_s^\xi \left[\lim_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T I_t^a \right] = \sum_{s' \in D \cap S} \frac{\bar{x}_{s'}}{\bar{x}_D} \cdot \xi(s')(a) = \frac{\bar{x}_{s'}}{\bar{x}_D} \cdot \frac{\bar{x}_a}{\bar{x}_{s'}} = \frac{\bar{x}_a}{\bar{x}_D}.$$

Because $|I_t^a| \leq 1$, Lebesgue Dominated convergence theorem (see, e.g. [15, Chapter 4, Section 4]) yields $\mathbb{E}_s^\xi \left[\lim_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T I_t^a \right] = \lim_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T \mathbb{E}_s^\xi [I_t^a]$ and thus $\text{freq}(\xi, s, a) = \frac{\bar{x}_a}{\bar{x}_D} = \text{freq}(\xi, D, a)$. This finishes the proof of Lemma 1.

2) *Proof of the equation (7):*

$$\begin{aligned} \mathbb{E}_{s_0}^\sigma [\text{lr}_{\inf}(r_i)] &= \mathbb{E}_{s_0}^\sigma \left[\liminf_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T r(A_t) \right] \\ &= \mathbb{E}_{s_0}^\sigma \left[\lim_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T r(A_t) \right] \\ &= \lim_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T \mathbb{E}_{s_0}^\sigma [r(A_t)] \\ &= \lim_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T \sum_{a \in A} r_i(a) \cdot \mathbb{P}_{s_0}^\sigma [A_t = a] \\ &= \sum_{a \in A} r_i(a) \cdot \lim_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T \mathbb{P}_{s_0}^\sigma [A_t = a] \\ &= \sum_{a \in A} r_i(a) \cdot \text{freq}(\sigma, s_0, a) \\ &= \sum_{a \in A} r_i(a) \cdot \bar{x}_a. \end{aligned}$$

Here the second equality follows from the fact that the limit is almost surely defined, following from the Ergodic theorem applied to the BSCCs of the finite Markov chain G^σ . The

third equality holds by Lebesgue Dominated convergence theorem, because $|r(A_t)| \leq \max_{a \in A} |r(a)|$. The seventh equality follows because $\text{freq}(\sigma, s_0, a) = \bar{x}_a$.

3) *Proof of the inequality (8):*

$$\begin{aligned} \sum_{a \in A} r_i(a) \cdot f(a) &= \sum_{a \in A} r_i(a) \cdot \lim_{\ell \rightarrow \infty} \frac{1}{T_\ell} \sum_{t=1}^{T_\ell} \mathbb{P}_{s_0}^\ell [A_t = a] \\ &= \lim_{\ell \rightarrow \infty} \frac{1}{T_\ell} \sum_{t=1}^{T_\ell} \sum_{a \in A} r_i(a) \cdot \mathbb{P}_{s_0}^\ell [A_t = a] \\ &\geq \liminf_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T \sum_{a \in A} r_i(a) \cdot \mathbb{P}_{s_0}^\ell [A_t = a] \\ &\geq \liminf_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T \mathbb{E}_{s_0}^\ell [r_i(A_t)] \\ &\geq \mathbb{E}_{s_0}^\ell [\text{lr}_{\inf}(r_i)]. \end{aligned}$$

Here, the first equality is the definition of $f(a)$, and the second follows from the linearity of the limit. The first inequality is the definition of \liminf . The second inequality relies on the linearity of the expectation, and the final inequality is a consequence of Fatou's lemma (see, e.g. [15, Chapter 4, Section 3]) – although the function $r_i(A_t)$ may not be non-negative, we can replace it with the non-negative function $r_i(A_t) - \min_{a \in A} r_i(a)$ and add the subtracted constant afterwards.

4) *Proof of the equation (9):*

$$\begin{aligned} \sum_{a \in A} f(a) \cdot \delta(a)(s) &= \sum_{a \in A} \lim_{\ell \rightarrow \infty} \frac{1}{T_\ell} \sum_{t=1}^{T_\ell} \mathbb{P}_{s_0}^\ell [A_t = a] \cdot \delta(a)(s) \\ &= \lim_{\ell \rightarrow \infty} \frac{1}{T_\ell} \sum_{t=1}^{T_\ell} \sum_{a \in A} \mathbb{P}_{s_0}^\ell [A_t = a] \cdot \delta(a)(s) \\ &= \lim_{\ell \rightarrow \infty} \frac{1}{T_\ell} \sum_{t=1}^{T_\ell} \mathbb{P}_{s_0}^\ell [S_{t+1} = s] \\ &= \lim_{\ell \rightarrow \infty} \frac{1}{T_\ell} \sum_{t=1}^{T_\ell} \mathbb{P}_{s_0}^\ell [S_t = s] \\ &= \lim_{\ell \rightarrow \infty} \frac{1}{T_\ell} \sum_{t=1}^{T_\ell} \sum_{a \in \text{Act}(s)} \mathbb{P}_{s_0}^\ell [A_t = a] \\ &= \sum_{a \in \text{Act}(s)} \lim_{\ell \rightarrow \infty} \frac{1}{T_\ell} \sum_{t=1}^{T_\ell} \mathbb{P}_{s_0}^\ell [A_t = a] \\ &= \sum_{a \in \text{Act}(s)} f(a). \end{aligned}$$

Here the first and the seventh equality follow from the definition of f . The second and the sixth equality follow from the linearity of the limit. The third equality follows by the

definition of δ . The fourth equality follows from the following:

$$\begin{aligned} & \lim_{\ell \rightarrow \infty} \frac{1}{T_\ell} \sum_{t=1}^{T_\ell} \mathbb{P}_{s_0}^\ell [S_{t+1} = s] - \lim_{\ell \rightarrow \infty} \frac{1}{T_\ell} \sum_{t=1}^{T_\ell} \mathbb{P}_{s_0}^\ell [S_t = s] \\ &= \lim_{\ell \rightarrow \infty} \frac{1}{T_\ell} \sum_{t=1}^{T_\ell} (\mathbb{P}_{s_0}^\ell [S_{t+1} = s] - \mathbb{P}_{s_0}^\ell [S_t = s]) \\ &= \lim_{\ell \rightarrow \infty} \frac{1}{T_\ell} (\mathbb{P}_{s_0}^\ell [S_{T_\ell+1} = s] - \mathbb{P}_{s_0}^\ell [S_1 = s]) = 0. \end{aligned}$$

5) *Proof of the existence of the strategy ζ :*

Lemma 2: Consider numbers \bar{y}_χ for all $\chi \in S \cup A$ such that the assignment $y_\chi := \bar{y}_\chi$ is a part of some non-negative solution to L . Then there is a finite-memory stochastic update strategy ζ which, starting from s_0 , stays eventually in each MEC C with probability $y_C := \sum_{s \in C} \bar{y}_s$.

Proof: As in the proofs of Propositions 1 and 2, in order to be able to use results of [6, Section 3] we modify the MDP G and obtain a new MDP G' as follows: For each state s we add a new absorbing state, d_s . The only available action for d_s leads to a loop transition back to d_s with probability 1. We also add a new action, a_s^d , to every $s \in S$. The distribution associated with a_s^d assigns probability 1 to d_s .

Let us call K the set of constraints of the LP on Figure 3 in [6]. From the values \bar{y}_χ we now construct a solution to K : for every state $s \in S$ and every action $a \in Act(s)$ we set $y_{(s,a)} := \bar{y}_a$, and $y_{(s,a_s^d)} := \bar{y}_s$. The values of the rest of variables in K are determined by the second set of equations in K . The non-negative constraints in K are satisfied since \bar{y}_χ are non-negative. Finally, the equations (1) from L imply that the first set of equations in K are satisfied, because \bar{y}_χ are part of a solution to L .

By Theorem 3.2 of [6] we thus have a memoryless strategy ϱ for G' such that $\mathbb{P}_\varrho^{s_0}[Reach(d_s)] \geq y_s$ for all $s \in S$. The strategy ζ then mimics the behavior of ϱ until the moment when ϱ chooses an action to enter some of the new absorbing states. From that point on, ζ may choose some arbitrary fixed behavior to stay in the current MEC. As a consequence: $\mathbb{P}_\zeta^{s_0}[\text{stay eventually in } C] \geq y_C$, and in fact, we get equality here, because of the equations (2) from L . Note that ζ only needs a finite constant amount of memory. ■

B. Proofs of Section V

Explanation of Proposition 3. The result that $\mathbb{P}_{s_0}^{\pi_1}[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}] > 0$ implies that there is a strategy π' such that $\mathbb{P}_{s_0}^{\pi'}[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}] = 1$ can be derived from the results of [2], [9] as follows. Since $\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}$ is a tail or prefix-independent function, it follows from the results of [2] that if $\mathbb{P}_{s_0}^{\pi_1}[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}] > 0$, then there exists a state s in the MDP with value 1, i.e., there exists s such that $\sup_\pi \mathbb{P}_s^\pi[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}] = 1$. It follows from the results of [9] that in MDPs with tail functions, optimal strategies exist and thus it follows that there exist a strategy π_1 from s such that $\mathbb{P}_{s_0}^{\pi_1}[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}] = 1$. Since the MDP is strongly connected, the state s can be reached with probability 1 from s_0 by a strategy π_2 . Hence the strategy π_2 , followed by the strategy

π_1 after reaching s , is the witness strategy π' such that $\mathbb{P}_{s_0}^{\pi'}[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}] = 1$.

1) *Proof of the inequality (12):*

$$\begin{aligned} & \sum_{a \in A} \text{freq}(\xi_\varepsilon, s_0, a) \cdot \vec{r}_i(a) \\ &= \sum_{a \in A} \frac{\bar{x}_a + x'_a}{X} \cdot \vec{r}_i(a) \quad (\text{def}) \\ &= \frac{1}{X} \cdot \sum_{a \in A} \bar{x}_a \cdot \vec{r}_i(a) + \frac{1}{X} \cdot \sum_{a \in A} x'_a \cdot \vec{r}_i(a) \quad (\text{rearranging}) \\ &= \left(\sum_{a \in A} \bar{x}_a \cdot \vec{r}_i(a) + \frac{1-X}{X} \cdot \sum_{a \in A} \bar{x}_a \cdot \vec{r}_i(a) \right) \\ &\quad + \frac{1}{X} \cdot \sum_{a \in A} x'_a \cdot \vec{r}_i(a) \quad (\text{rearranging}) \\ &\geq \sum_{a \in A} \bar{x}_a \cdot \vec{r}_i(a) - \left| \frac{1-X}{X} \cdot \sum_{a \in A} \bar{x}_a \cdot \vec{r}_i(a) \right| \\ &\quad - \left| \frac{1}{X} \cdot \sum_{a \in A} x'_a \cdot \vec{r}_i(a) \right| \quad (\text{property of abs. value}) \\ &\geq \sum_{a \in A} \bar{x}_a \cdot \vec{r}_i(a) \\ &\quad - \left(\left| (1-X) \cdot \sum_{a \in A} \bar{x}_a \cdot \vec{r}_i(a) \right| + \left| \sum_{a \in A} x'_a \cdot \vec{r}_i(a) \right| \right) \\ &\quad (\text{from } X > 1) \\ &\geq \sum_{a \in A} \bar{x}_a \cdot \vec{r}_i(a) \\ &\quad - \left((1-X) \cdot \sum_{a \in A} \bar{x}_a \cdot |\vec{r}_i(a)| + \sum_{a \in A} x'_a \cdot |\vec{r}_i(a)| \right) \\ &\quad (\text{property of abs. value and } X > 1) \\ &\geq \sum_{a \in A} \bar{x}_a \cdot \vec{r}_i(a) \\ &\quad - \left((1-X) \cdot M_r + \sum_{a \in A} x'_a \cdot M_r \right) \quad (\text{property of } M_r) \\ &\geq \sum_{a \in A} \bar{x}_a \cdot \vec{r}_i(a) \\ &\quad - \left(\left(\sum_{a \in A} x'_a \right) \cdot M_r + \left(\sum_{a \in A} x'_a \right) \cdot M_r \right) \\ &\quad (\text{property of } X \text{ and rearranging}) \\ &= \sum_{a \in A} \bar{x}_a \cdot \vec{r}_i(a) - 2 \cdot \left(\sum_{a \in A} x'_a \right) \cdot M_r \quad (\text{rearranging}) \\ &\geq \vec{v}_i - 2 \cdot \left(\sum_{a \in A} x'_a \right) \cdot M_r \quad (\text{property of } \vec{v}) \\ &\geq \vec{v}_i - \varepsilon \quad (\text{property of } \varepsilon) \end{aligned}$$

2) *Proof of the inequality (13):* First, note that

$$\frac{1}{T} \sum_{t=0}^T I_a(a_t) \geq \frac{1}{T} \sum_{t=N_i-1}^{N_i-1} I_a(a_t) + \frac{1}{T} \sum_{t=N_i}^T I_a(a_t)$$

and that

$$\frac{1}{T} \sum_{t=N_i-1}^{N_i-1} I_a(a_t) = \frac{1}{n_i} \sum_{t=N_i-1}^{N_i-1} I_a(a_t) \cdot \frac{n_i}{T} \geq (\bar{x}_a - 2^{-i}) \frac{n_i}{T}$$

which gives

$$\frac{1}{T} \sum_{t=0}^T I_a(a_t) \geq (\bar{x}_a - 2^{-i}) \frac{n_i}{T} + \frac{1}{T} \sum_{t=N_i}^T I_a(a_t). \quad (14)$$

Now, we distinguish two cases. First, if $T - N_i \leq \kappa_{i+1}$, then

$$\frac{n_i}{T} \geq \frac{n_i}{N_{i-1} + n_i + \kappa_{i+1}} = 1 - \frac{N_{i-1} + \kappa_{i+1}}{N_{i-1} + n_i + \kappa_{i+1}} \geq (1 - 2^{1-i})$$

and thus, by Equation (14),

$$\frac{1}{T} \sum_{t=0}^T I_a(a_t) \geq (\bar{x}_a - 2^{-i})(1 - 2^{1-i}).$$

Second, if $T - N_i \geq \kappa_{i+1}$, then

$$\begin{aligned} \frac{1}{T} \sum_{t=N_i+1}^T I_a(a_t) &= \frac{1}{T - N_i} \sum_{t=N_i+1}^T I_a(a_t) \cdot \frac{T - N_i}{T} \\ &\geq (\bar{x}_a - 2^{-i-1}) \left(1 - \frac{N_{i-1} + n_i}{T}\right) \\ &\geq (\bar{x}_a - 2^{-i-1}) \left(1 - 2^{-i} - \frac{n_i}{T}\right) \end{aligned}$$

and thus, by Equation (14),

$$\begin{aligned} \frac{1}{T} \sum_{t=0}^T I_a(a_t) &\geq (\bar{x}_a - 2^{-i}) \frac{n_i}{T} + (\bar{x}_a - 2^{-i-1}) \left(1 - 2^{-i} - \frac{n_i}{T}\right) \\ &\geq (\bar{x}_a - 2^{-i}) \left(\frac{n_i}{T} + \left(1 - 2^{-i} - \frac{n_i}{T}\right)\right) \\ &\geq (\bar{x}_a - 2^{-i})(1 - 2^{-i}) \end{aligned}$$

which finishes the proof of (13).

C. Deterministic-update Strategies for Expectation Objectives

Recall the system L of linear inequalities presented on Figure 2 on page 6.

Proposition 4: Every nonnegative solution of the system L induces a finite-memory deterministic-update strategy σ satisfying $\mathbb{E}_{s_0}^{\sigma}[\text{lr}_{\text{inf}}(\vec{r})] \geq \vec{v}$.

Proof: The proof proceeds almost identically to the proof of Proposition 1. Let us recall the important steps from the said proof first. There we worked with the numbers \bar{x}_a , $a \in A$, which, assigned to the variables x_a , formed a part of the solution to L . We also worked with two important strategies. The first one, a finite-memory deterministic-update strategy ζ , made sure that, starting in s_0 , a run stays in a MEC C forever with probability $y_C = \sum_{a \in A \cap C} \bar{x}_a$. The second one, a memoryless strategy σ' , had the property that when the starting distribution was $\alpha(s) := \bar{x}_s = \sum_{a \in \text{Act}(s)} \bar{x}_a$ then $\mathbb{E}_{\alpha}^{\sigma'}[\text{lr}_{\text{inf}}(\vec{r})] \geq \vec{v}$.¹ To produce the promised finite-memory deterministic-update strategy σ we now have to combine the strategies ζ and σ' using only deterministic memory updates.

We now define the strategy σ . It works in three phases. First, it reaches every MEC C and stays in it with the probability y_C . Second, it prepares the distribution α , and finally third, it switches to σ' . It is clear how the strategy is defined in the third

¹Here we extend the notation in a straightforward way from a single initial state to a general initial distribution, α .

Fig. 3: MDP for Appendix D

phase. As for the first phase, this is also identical to what we did in the proof of Proposition 1 for $\bar{\sigma}$: The strategy σ follows the strategy ζ from beginning until the associated finite state Markov chain G^{ζ} a bottom strongly connected component (BSCC) is reached. At that point the run has already entered its final MEC C to stay in it forever, which happens with probability y_C .

The last thing to solve is thus the second phase. Two cases may occur. Either there is a state $s \in C$ such that $|\text{Act}(s) \cap C| > 1$, i.e., there are at least two actions the strategy can take from s without leaving C . Let us denote these actions a and b . Consider an enumeration $C = \{s_1, \dots, s_k\}$ of vertices of C . Now we define the second phase of σ when in C . We start with defining the memory used in the second phase. We symbolically represent the possible contents of the memory as $\{\text{WAIT}_1, \dots, \text{WAIT}_k, \text{SWITCH}_1, \dots, \text{SWITCH}_k\}$. The second phase then starts with the memory set to WAIT_1 . Generally, if the memory is set to WAIT_i then σ aims at reaching s with probability 1. This is possible (since s is in the same MEC) and it is a well known fact that it can be done without using memory. On visiting s , the strategy chooses the action a with probability $\bar{x}_{s_i}/(y_C - \sum_{j=1}^{i-1} \bar{x}_{s_j})$ and the action b with the remaining probability. In the next step the deterministic update function sets the memory either to SWITCH_i or WAIT_{i+1} , depending on whether the last action seen is a or b , respectively. (Observe that if $i = k$ then the probability of taking b is 0.) The memory set to SWITCH_i means that the strategy aims at reaching s_i almost surely, and upon doing so, the strategy switches to the third phase, following σ' . It is easy to observe that on the condition of staying in C the probability of switching to the third phase in some $s_i \in C$ is \bar{x}_{s_i}/y_C , thus the unconditioned probability of doing so is \bar{x}_{s_i} , as desired.

The remaining case to solve is when $|\text{Act}(s) \cap C| = 1$ for all $s \in C$. But then switching to the third phase is solved trivially with the right probabilities, because staying in C inevitably already means mimicking σ' . ■

D. Sufficiency of Strategies for Satisfaction Objectives

Lemma 3: There is an MDP G a vector of reward functions $\vec{r} = (r_1, r_2)$, and a vector $(\nu, \vec{v}) \in \text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$ such that there is no finite-memory strategy σ satisfying $\mathbb{P}_s^{\sigma}[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v}] > \nu$.

Proof: We let G be the MDP from Fig. 3, and the reward function r_i (for $i \in \{1, 2\}$) returns 1 for b_i and 0 for all other actions. Let s_1 be the initial vertex. It is easy to see that $(0.5, 0.5) \in \text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$: consider for example a strategy that first chooses both available actions in s_1 with uniform probabilities, and in subsequent steps chooses self-loops on s_1 or s_2 deterministically. From the results of Section V we subsequently get that $(1, 0.5, 0.5) \in \text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$.

On the other hand, let σ be arbitrary finite-memory strategy. The Markov chain it induces is by definition finite and for each of its BSCC C we have the following. One of the following then takes place:

- C contains both s_1 and s_2 . Then by Ergodic theorem for almost every run ω we have $\text{lr}(I_{a_1}, \omega) + \text{lr}(I_{a_2}, \omega) > 0$, which means that $\text{lr}(I_{b_1}, \omega) + \text{lr}(I_{b_2}, \omega) < 1$, and thus necessarily $\text{lr}_{\text{inf}}(\vec{r}, \omega) \not\geq (0.5, 0.5)$.
- C contains only the state s_1 (resp. s_2), in which case all runs that enter it satisfy $\text{lr}_{\text{inf}}(\vec{r}, \omega) < (1, 0)$ (resp. $\text{lr}_{\text{inf}}(\vec{r}, \omega) = (0, 1)$).

From the basic results of the theory of Markov chains we get $\mathbb{P}_{s_1}^\sigma[\text{lr}_{\text{inf}}(\vec{r}) \geq (0.5, 0.5)] = 0$. ■

Lemma 4: There is an MDP G a vector of reward functions $\vec{r} = (r_1, r_2)$, a number $\varepsilon > 0$ and a vector $(\nu, \vec{v}) \in \text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$ such that there is no memoryless-pure strategy σ satisfying $\mathbb{P}_s^\sigma[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v} - \vec{\varepsilon}] > \nu - \vec{\varepsilon}$.

Proof: We can reuse G and \vec{r} from the proof of Lemma 3. We let $\nu = 1$ and $\vec{v} = (0.5, 0.5)$. We have shown that $(\nu, \vec{v}) \in \text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$. Taking e.g. $\varepsilon = 0.1$, it is a trivial observation that no memoryless pure strategy satisfies $\mathbb{P}_s^\sigma[\text{lr}_{\text{inf}}(\vec{r}) \geq \vec{v} - \vec{\varepsilon}] > \nu - \vec{\varepsilon}$. ■

E. Equivalence of Definitions of Strategies

In this section we argue that the definitions of strategies as functions $(SA)^*S \rightarrow \text{dist}(A)$ and as triples $(\sigma_u, \sigma_n, \alpha)$ are interchangeable.

Note that formally a strategy $\pi : (SA)^*S \rightarrow \text{dist}(A)$ gives rise to a Markov chain G^π with states $(SA)^*S$ and transitions $w \xrightarrow{\sigma(w)(a), \delta(a)(s)} was$ for all $w \in (SA)^*S$, $a \in A$ and $s \in S$. Given $\sigma = (\sigma_u, \sigma_n, \alpha)$ and a run $w = (s_0, m_0, a_0)(s_1, m_1, a_1) \dots$ of G^σ denote $w[i] = s_0 a_0 s_1 a_1 \dots s_{i-1} a_{i-1} s_i$. We define $f(w) = w[0]w[1]w[2] \dots$

We need to show that for every strategy $\sigma = (\sigma_u, \sigma_n, \alpha)$ there is a strategy $\pi : (SA)^*S \rightarrow \text{dist}(A)$ (and vice versa) such that for every set of runs W of G^π we have $\mathbb{P}_{s_0}^\sigma[f^{-1}(W)] = \mathbb{P}_{s_0}^\pi[W]$. We only present the construction of strategies and basic arguments, the technical part of the proof is straightforward.

Given $\pi : (SA)^*S \rightarrow \text{dist}(A)$, one can easily define a *deterministic-update* strategy $\sigma = (\sigma_u, \sigma_n, \alpha)$ which uses memory $(SA)^*S$. The initial memory element is the initial state s_0 , the next move function is defined by $\sigma(s, w) = \pi(w)$, and the memory update function σ_u is defined by $\sigma_u(a, s, w) = was$. Reader can observe that there is a naturally defined bijection between runs in G^π and in G^σ , and that this bijection preserves probabilities of sets of runs.

In the opposite direction, given $\sigma = (\sigma_u, \sigma_n, \alpha)$, we define $\pi : (SA)^*S \rightarrow \text{dist}(A)$ as follows. Given $w = s_0 a_0 \dots s_{n-1} a_{n-1} s_n \in (SA)^*S$ and $a \in A$, we denote U_a^w the set of all paths in G^σ that have the form

$$(s_0, m_0, a_0)(s_1, m_1, a_1) \dots (s_{n-1}, m_{n-1}, a_{n-1})(s_n, m_n, a)$$

for some m_1, \dots, m_n . We put $\pi(w)(a) = \frac{\mathbb{P}_{s_0}^\sigma[U_a^w]}{\sum_{a' \in A} \mathbb{P}_{s_0}^\sigma[U_{a'}^w]}$. The key observation for the proof of correctness of this

construction is that the probability of U_a^w in G^σ is equal to probability of taking a path w and then an action a in G^π .

F. Details from the proof of B.6

Here we prove the rest of B.6. We start with proving that the set $N := \{\nu \mid (\nu, \vec{v}) \in P\}$, where P is the Pareto curve for $\text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$, is indeed finite. As we already showed, for every fixed \vec{v} there is a union \mathcal{C} of MECs good for \vec{v} , and $(\nu, \vec{v}) \in \text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))$ iff the \mathcal{C} can be reached with probability at least ν . Hence $|N| \leq 2^{|G|}$, because the latter is an upper bound on a number of unions of MECs in G .

To proceed with the proof of B.6, let us consider a fixed $\nu \in N$. This gives us a collection $R(\nu)$ of all unions \mathcal{C} of MECs which can be reached with probability at least ν . For a MEC C let $\text{Sol}(C)$ be the set $\text{AcEx}(\text{lr}_{\text{inf}}(\vec{r}))$ of the MDP given by restricting G to C . Further, for every $\mathcal{C} \in R(\nu)$ we set $\text{Sol}(\mathcal{C}) := \bigcap_{C \in \mathcal{C}} \text{Sol}(C)$. Finally, $\text{Sol}(R(\nu)) := \bigcup_{\mathcal{C} \in R(\nu)} \text{Sol}(\mathcal{C})$. From the analysis above we already know that $\text{Sol}(R(\nu)) = \{\vec{v} \mid (\nu, \vec{v}) \in \text{AcSt}(\text{lr}_{\text{inf}}(\vec{r}))\}$. As a consequence, $(\nu, \vec{v}) \in P$ iff $\nu \in N$ and \vec{v} is maximal in $\text{Sol}(R(\nu))$ and $\vec{v} \notin \text{Sol}(R(\nu'))$ for any $\nu' \in N$, $\nu' > \nu$. In other words, P is also the Pareto curve of the set $Q := \{(\nu, \vec{v}) \mid \nu \in N, \vec{v} \in \text{Sol}(R(\nu))\}$. Observe that Q is a finite union of bounded convex polytopes, because every $\text{Sol}(C)$ is a bounded convex polytope. Finally, observe that N can be computed using the algorithms for optimizing single-objective reachability. Further, the inequalities defining $\text{Sol}(C)$ can also be computed using our results on AcEx . By a *generalised convex polytope* we denote a set of points described by a finite conjunction of linear inequalities, which may be both strict and non-strict.

Claim 1: Let X be a generalised convex polytope. The smallest convex polytope containing X is its closure, $\text{cl}(X)$. Moreover, the set $\text{cl}(X) \setminus X$ is a union of some of the facets of $\text{cl}(X)$.

Proof: Let I be the set of inequalities defining X , and denote by I' the modification of this set where all the inequalities are transformed to non-strict ones. The closure $\text{cl}(X)$ indeed is a convex polytope, as it is described by I' . Since every convex polytope is closed, if it contains X then it must contain also its closure. Thus $\text{cl}(X)$ is the smallest one containing X . Let $\alpha < \beta$ be a strict inequality from I . By $I'(\alpha = \beta)$ we denote the set $I' \cup \{\alpha = \beta\}$. The points of $\text{cl}(X) \setminus X$ form a union of convex polytopes, each one given by the set $I'(\alpha = \beta)$ for some $\alpha < \beta \in I$. Thus, it is a union of facets of $\text{cl}(X)$. ■

The following lemma now finishes the proof of B.6:

Lemma 5: Let Q be a finite union of bounded convex polytopes, Q_1, \dots, Q_m . Then its Pareto curve, P , is a finite union of bounded generalised convex polytopes, P_1, \dots, P_n . Moreover, if the inequalities describing Q_i are given, then the inequalities describing P_i can be computed.

Proof: We proceed by induction on the number m of components of Q . If $m = 0$ then $P = \emptyset$ is clearly a bounded convex polytope easily described by arbitrary two incompatible inequalities. For $m \geq 1$ we denote set $Q' := \bigcup_{i=1}^{m-1} Q_i$. By the induction hypothesis, the Pareto curve of Q' is some

$P' := \bigcup_{i=1}^{n'} P_i$ where every P_i , $1 \leq i \leq n'$ is a bounded generalised convex polytope, described by some set of linear inequalities. Denote by $dom(X)$ the (downward closed) set of all points dominated by some point of X . Observe that P , the Pareto curve of Q , is the union of all points which either are maximal in Q_m and do not belong to $dom(P')$ (observe that $dom(P') = dom(Q')$), or are in P' and do not belong to $dom(Q_m)$. In symbols:

$$P = (\text{maximal from } Q_m \setminus dom(P')) \cup (P' \setminus dom(Q_m)).$$

The set $dom(P')$ of all \vec{x} for which there is some $\vec{y} \in P'$ such that $\vec{y} \geq \vec{x}$ is a union of projections of generalised convex polytopes – just add the inequalities from the definition of each P_i instantiated with \vec{y} to the inequality $\vec{y} \geq \vec{x}$, and remove \vec{x} by projecting. Thus, $dom(P')$ is a union of generalised convex polytopes itself. A difference of two generalised convex polytopes is a union of generalised convex polytopes. Thus the set “maximal from $Q_m \setminus dom(P')$ ” is a union of generalised bounded convex polytopes, and for the same reasons so is $P' \setminus dom(Q_m)$.

Finally, let us show how to compute P . This amounts to computing the projection, and the set difference. For convex polytopes, efficient computing of projections is a problem studied since the 19th century. One of possible approaches,

non-optimal from the complexity point of view, but easy to explain, is by traversing the vertices of the convex polytope and projecting them individually, and then taking the convex hull of those vertices. To compute a projection of a generalised convex polytope X , we first take its closure $cl(X)$, and project the closure. Then we traverse all the facets of the projection and mark every facet to which at least one point of X is projected. This can be verified by testing whether the inequalities defining the facet in conjunction with the inequalities defining X have a solution. Finally, we remove from the projection all facets which are not marked. Due to Claim 1, the difference of the projection of $cl(X)$ and the projection of X is a union of facets. Every facet from the difference has the property that no point from X is projected to it. Thus we obtained the projection of X .

Computing the set difference of two bounded generalised convex polytopes is easier: Consider we have two polytopes, given by sets I_1 and I_2 of inequalities. Then subtracting the second generalised convex polytope from the first is the union of generalised polytopes given by the inequalities $I_1 \cup \{\alpha \not\prec \beta\}$, where $\alpha \prec \beta$ ranges over all inequalities (strict or non-strict) in I_2 . ■
